Abstract

There is substantial interest in restoring tidal wetlands because of their high rates of long-term soil carbon sequestration and other valued ecosystem services. However, these wetlands are sometimes net sources of greenhouse gases (GHG) that may offset their climate cooling potential. GHG fluxes vary widely within and across tidal wetlands, so it is essential to better understand how key environmental drivers, and importantly, land management, affect GHG dynamics. We measured methane (CH₄) and nitrous oxide (N₂O) fluxes at 26 reference and restored tidal wetland sites and eight nontidal pastures (mostly diked former tidal wetlands) in five estuaries in the Pacific Northwest (PNW), USA. We measured fluxes 7–8 times over one year to assess the effects of environmental drivers, wetland type, and land management on CH₄ and N₂O fluxes. Linear relationships between CH₄ fluxes and environmental drivers were poor, but a machine-learning approach with boosted regression trees provided strong predictability for fluxes based upon wetland surface elevation, water-table level, and salinity. Less important variables were groundwater pH, wetland type, and temperature. Under oligohaline conditions, CH₄ fluxes were variable and sometimes very high, but fluxes at salinities above 2 ppt were relatively low on an annual basis. Fluxes of CH₄ were higher in restored tidal marshes and wet pastures than in reference tidal marshes, tidal swamps, and dry pastures. The N₂O model had lower predictive power than the CH₄ model, with wetland type as the most important factor, although N₂O fluxes across all wetland types were low (median of zero). Our results indicate that estuarine hydrologic gradients are a key driver of CH₄ fluxes and that wetland land use impacts on CH₄ fluxes are largely mediated by their varying environmental conditions. In the PNW, estuarine wetlands that have low salinity, lower elevation, and have high water tables are more likely to have increased CH₄ emissions that may offset their carbon sequestration benefits until they gain enough elevation through accretion. This study also provides a

transferrable modeling approach to predict the consequences of coastal wetland management on GHG fluxes using monitoring data from a limited set of key environmental drivers.

boosted regression trees, estuaries, methane, natural climate solutions, nitrous oxide, restoration, tidal marsh, tidal swamp

INTRODUCTION

Global efforts to find natural adaptive solutions to help mitigate anthropogenic climate change have increased attention on coastal tidal wetlands, including emergent marshes, seagrass meadows, mangrove forests, and temperate tidal swamps, because of their ability to remove and store carbon dioxide effectively (McLeod et al., 2011). These “blue carbon” ecosystems are highly efficient, on a per-unit-area rate basis, at sequestering organic carbon derived from both in situ photosynthetic production and allochthonous carbon inputs from coastal watersheds (Chmura et al., 2003; Hopkinson et al., 2012; Kauffman et al., 2020; Peck et al., 2020; Poppe & Rybczyk, 2021). Interest in blue carbon has led to growing incentives for governments and land managers to conserve and restore tidal wetlands over the past decade (Kelleway et al., 2020), actions which have the added benefits of increasing habitat for fish and wildlife, providing flood protection, and sustaining the important cultural and biodiversity services of estuaries (David et al., 2014; Himes-Cornell et al., 2018).

Although blue carbon ecosystems have a high capacity to sequester organic carbon, they also can emit the powerful greenhouse gases (GHGs) methane (CH_4) and nitrous oxide (N_2O), potentially offsetting their cooling potential. Saline and brackish tidal wetlands are estimated to emit globally $0.76 \text{ Tg CH}_4 \text{ year}^{-1}$ with much smaller emissions of $6.3 \text{ Gg N}_2\text{O year}^{-1}$, but these GHG emissions are offset by soil carbon sequestration, so there is an estimated global net removal of $538 \text{ Tg CO}_2 \text{ eq. year}^{-1}$ using a 20-year global warming potential (Rosentreter et al., 2023). However, the range of GHG emissions observed both globally and regionally is large because CH_4 and N_2O production in wetlands is affected by a number of drivers conferring high heterogeneity in time and space (Capooci & Vargas, 2022; Hemes et al., 2018; Rosentreter et al., 2021). Global wetland CH_4 emissions also may have increased over the last two decades due to feedback from increasing air temperatures and precipitation (Zhang et al., 2023). It is important to understand how coastal land management affects GHG fluxes in estuarine wetlands because perceived positive climate forcing benefits may be a motivating factor in

new restoration projects. Understanding how CH_4 and N_2O fluxes differ along key estuarine environmental gradients and among different management histories is crucial for determining to what extent these ecosystems can contribute to a suite of natural climate solutions that help mitigate global warming.

Variability in estuarine biogeophysical conditions influences CH_4 fluxes in tidal wetlands, with water-table level, salinity, and temperature being major factors (Rosentreter et al., 2021; Schultz et al., 2023; Tan et al., 2020). Low salinity wetlands emit higher and more variable levels of CH_4 (Poffenbarger et al., 2011; Sanders-DeMott et al., 2022), and 18 ppt (about half the concentration of seawater) is often used as a threshold between high- and low-emission tidal wetlands (IPCC, 2014). Controls on CH_4 fluxes at lower salinities are more complex and involve multiple environmental drivers that may be nonlinear and interact with one another (Schultz et al., 2023). New modeling techniques such as machine-learning approaches that account for nonlinear and interactive effects of multiple environmental drivers can help researchers better predict GHG fluxes when there are potentially complex controls operating at multiple spatial and temporal scales (Schultz et al., 2023; Yuan et al., 2022).

Two recent meta-analyses found disparate results regarding the effects of coastal wetland conversion to other land uses, and subsequent restoration, on CH_4 and N_2O fluxes (O'Connor et al., 2020; Tan et al., 2020). This emphasizes the need for further studies. Along the US west coast, many tidal wetlands were historically diked, drained, and converted to agricultural uses, resulting in high levels of wetland loss and fragmentation of estuarine landscapes (Brophy et al., 2019; Marcoe & Pilson, 2017). To reverse loss and enhance estuarine function, efforts to restore tidal wetlands, particularly emergent marshes, are increasing all along the US west coast. From a blue carbon perspective, it is crucial to understand how land management practices such as diking and subsequent draining and seasonal drying of tidal wetland soils may contribute to changes in CH_4 and N_2O production to inform accurate assessments of the overall climate effects of wetland conservation and restoration. Moreover, it is

necessary to determine how GHG fluxes may change in restored sites over longer time scales as site conditions such as hydrology evolve. However, very little data exist on GHG fluxes in natural, disturbed, or restored tidal wetlands in the Pacific Northwest (PNW) region of the United States (Diefenderfer et al., 2018a; RoyChowdhury et al., 2018; Schultz et al., 2023).

We conducted a regional assessment of CH₄ and N₂O fluxes from tidal wetlands across a range of land management regimes and wetland types in the PNW using a machine-learning approach to examine the relative impacts of environmental drivers on fluxes and to predict annual fluxes at the site level. Our study builds on more localized research in the region using a similar approach (Schultz et al., 2023). We measured GHG fluxes in least-disturbed reference tidal marshes and swamps, restored tidal marshes, and nontidal pastures (mainly former tidal wetlands historically converted to agricultural land uses). At the same sites, we also measured environmental factors likely to affect fluxes, including water-table level, groundwater salinity and pH, soil and air temperature, and plant biomass and species composition. This study tested the following hypotheses: (1) CH₄ fluxes increase with greater waterlogging, lower salinity, and higher soil and air temperatures. (2) CH₄ trends related to environmental drivers are nonlinear and interactive. (3) Plant biomass and community composition affect GHG fluxes. (4) CH₄ fluxes differ among estuarine wetland types and land management regimes, which can largely be explained by their effects on ecosystem drivers of these fluxes. (5) N₂O fluxes are low overall but are somewhat higher in former tidal wetlands now used for agriculture. By incorporating a large regional dataset into a machine learning model, we developed a framework that can be applied to estimating fluxes from other estuarine wetlands in the region where flux data are not available.

MATERIALS AND METHODS

Study sites

We measured GHG fluxes at 34 sites in estuaries on the Oregon and Washington coasts 7–8 times from spring 2021 to spring 2022, which differed in dominant vegetation, disturbance status, tide range, and salinity. Sites were located in the Coos Estuary (OR), Columbia River Estuary (OR/WA), Grays Harbor Estuary (WA), Skagit Estuary (WA), and Padilla Bay (WA) (Figure 1A; Appendix S1: Table S1). Sites included 12 reference marshes, five forested tidal swamps, nine restored marshes, and eight nontidal pastures. The nine restored sites ranged in age from about 5 to 25 years at the time of sampling

and were mostly dike breaches or removals to restore tidal connectivity. Tidal sites occurred across a broad continuum of salinity from tidal freshwater marshes and swamps in the Columbia River and Skagit estuaries (0–0.5 ppt) to oligohaline (0.5–5 ppt), mesohaline (5–18 ppt), and polyhaline conditions (18–30 ppt) in other estuaries. Marshes were dominated by a mixture of mostly perennial grasses, sedges, and forbs, while tidal swamps were dominated by trees (mainly *Picea sitchensis*) with woody and herbaceous understories. Pastures were nontidal sites dominated by graminoid emergent vegetation and included six diked former tidal wetlands (two were being agriculturally managed and four were not at the time of sampling) and two in a coastal floodplain adjacent to estuarine wetlands but at elevations mostly above tidal influence. We classified three pastures as “wet pastures” (median water table 25 cm below the surface or higher for at least 5 month out of the year) and the other five sites as “dry pastures.” We combined wetland types and land management classes into a single class termed “wetland type” for brevity.

Gas sampling

At each site, we inserted six PVC collars (40 cm diameter, 16 cm height) about 9 cm into the ground for the duration of the study. Drainage ports were inserted when necessary to facilitate drainage. Collars were situated at both ends of 2.4-m-long wood boardwalks that were used to minimize sediment disturbance near the collars during sampling (Figure 1B). At most sites, the three boardwalks were arranged along a short transect perpendicular to a major tidal slough (or ditch or stream in the case of nontidal pastures) in order to capture gradients within sites due to differences in elevation, hydrology, and plant composition. At tidal swamp sites, because of the complex physical structure caused by tree roots and stumps, we installed the boardwalks in relatively flat areas.

At the time of sampling, we fitted collars with one or more 0.04 m³ chamber tops (multiple top sections were stacked to accommodate tall vegetation) constructed from a PVC frame and 6-mil (i.e., 0.152 mm thickness) translucent greenhouse plastic affixed with clear adhesive tape to form an airtight seal. We drilled an intake port at the top and a return port at the bottom, installed with Swagelok fixtures, and connected to tubing that ran to the gas analyzer, creating a closed-loop system. Given the large number of widely dispersed sites, two teams were responsible for gas measurements, and a comparison of the two instruments gave similar slopes for CH₄ fluxes. We sampled the southern estuaries (Coos Bay and Columbia River) with a portable Fourier-transform infrared

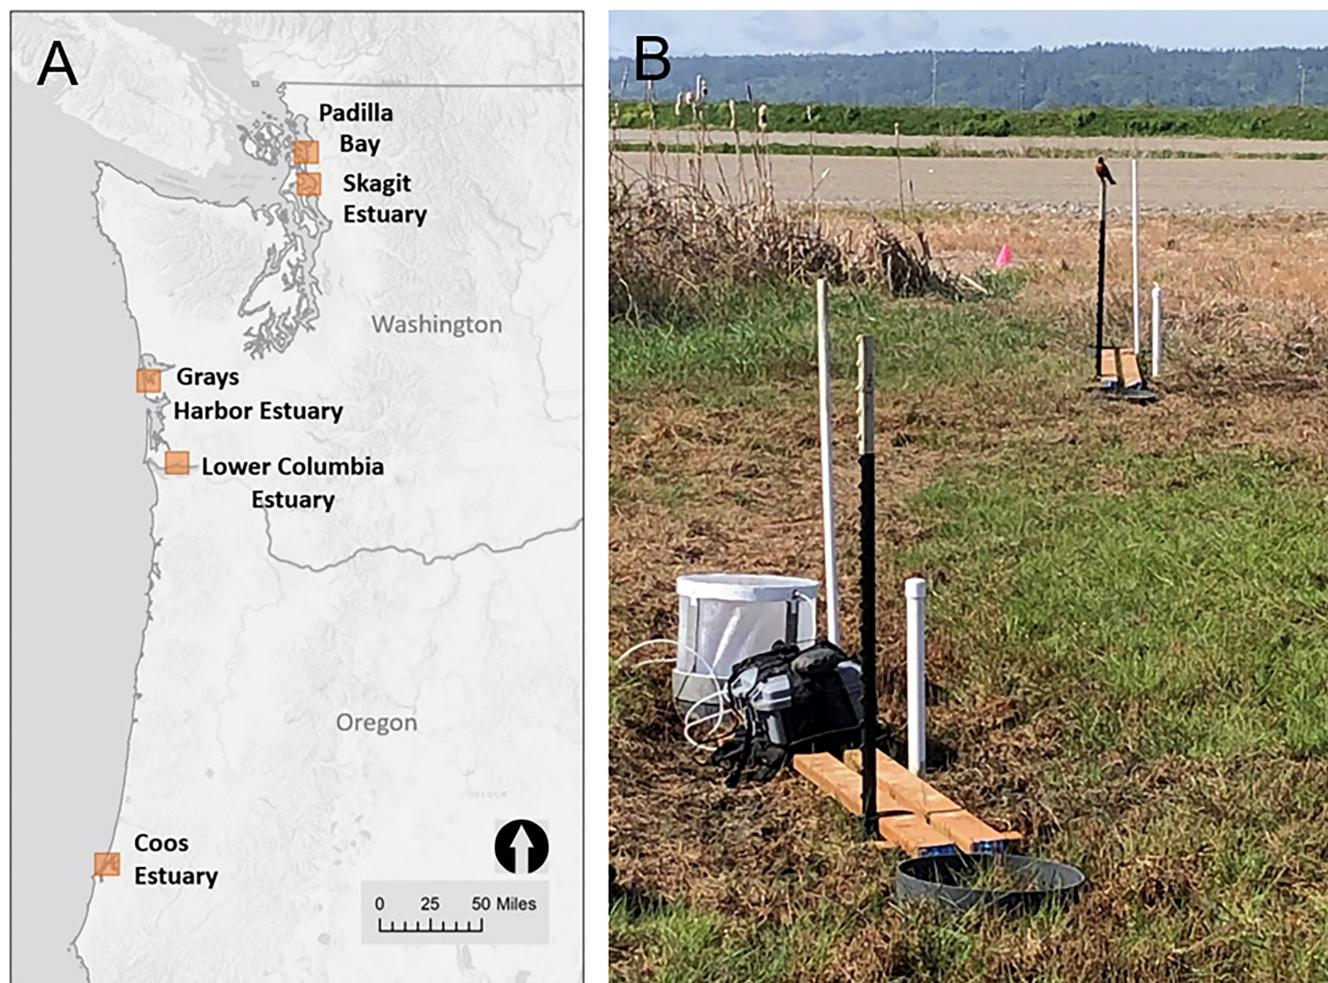

FIGURE 1 (A) Map of the five study estuaries in Oregon and Washington, USA, and (B) example collar, boardwalk, and chamber setup at a nontidal pasture site in Padilla Bay. Photograph by M. McKeon. Map by C. Cornu.

(FTIR) gas analyzer, Gasetm DX4040 (Vantaa, Finland), and the northern estuaries (Grays Harbor, Skagit, Padilla Bay) with an Optical Feedback—Cavity Enhanced Absorption Spectroscopy (OF-CEAS) gas analyzer, LI-7810 (LI-COR, Lincoln, NE, USA) (Figure 1B). Only the Gasetm allowed for N_2O flux measurements. The Gasetm was out of service for several months, during which time we used the LI-7810 on all sites. Since N_2O sampling was limited to sites and months when the Gasetm was operational, the dataset has about a third as many measurements as CH_4 .

Battery-operated fans placed inside of the chambers mixed the headspace. We conducted light and dark measurements sequentially at each chamber to determine if light availability affected fluxes. We determined dark fluxes by placing black plastic sheeting over the chamber tops and measuring gas concentrations for approximately 6 min. We then removed the chamber tops, allowed gas concentrations to return to ambient levels, and replaced the chamber tops for light measurements for another

6 min. The LI-COR sampled continuously at about 1 Hz, and the Gasetm samples were averaged every 30 s.

We determined the linear slopes of the change in GHG concentrations during light and dark periods to calculate flux rates. When linear slopes were non-significant ($R^2 < 0.33$ and $p > 0.05$), we concluded that fluxes were below the detection limit. Because the LI-COR instrument collected data at a much higher frequency than the Gasetm analyzer, almost all slopes from the former had a significant p -value, so the strength of the relationship (R^2) was the primary determinant of linearity with that instrument.

Environmental data

We installed one shallow groundwater well per pair of collars (three per site) to obtain spot measurements of water-table level, water temperature, salinity, and pH at each gas sampling. These wells consisted of 1-m-long,

3-cm-diameter PVC pipes inserted halfway into the ground with drilled holes for the bottom 40 cm of the well to allow groundwater flow. At each GHG sampling event, we made measurements inside of the wells with YSI Pro 30 conductivity meters (YSI Incorporated, Yellow Springs, OH) for salinity and Extech PH220 or Apera PH60 sensors for pH. Water-table measurements were individualized in the two chambers per boardwalk by measuring their respective elevations relative to the main groundwater well (see below).

We also established a single deeper (1.0–1.5 m) groundwater well at each site, typically located 15–20 m away from a major tidal creek or channel but relatively close to each transect, to obtain a detailed time series of groundwater conditions. These wells were constructed from 5-cm-diameter PVC pipe and well screen. Inside of each well, we added a Hobo U20 or U20L (Onset Corporation, Bourne, MA) water-level sensor, suspended near the bottom of the well at a known distance below ground to record water-table level every 30 min. We also suspended an Odyssey conductivity and temperature logger (Dataflow Systems Ltd., Christchurch, NZ) about 25 cm below the ground surface to record salinity and temperature in the root zone every 30 min. In addition, we obtained a time series of soil temperature at each site by burying a Hobo pendant UA-001-08 logger 5 cm below ground and recording values every hour. During the >1 year time series of soil temperature and groundwater conditions measured at each site, we periodically downloaded and cleaned loggers. We also checked for logger accuracy under controlled conditions before their use in the field and verified logger salinity and temperature values with in situ checks performed with a YSI Pro30 conductivity probe. In a few freshwater sites, we did not deploy Odyssey loggers in the groundwater wells but did record salinity values with intermittent YSI Pro30 measurements.

Elevation

We determined the elevation of the wetland surface at each GHG collar and groundwater well using real-time kinematic global navigation satellite system (RTK-GNSS) methods with Trimble R8 and R12 rovers (Trimble, Inc., Westminster, CO) connected to real-time correction networks (ORGN in Oregon and southwest Washington and WSRN in the rest of Washington). For sites with significant tree cover, we determined elevations using laser leveling from nearby temporary benchmarks measured with RTK-GNSS. We obtained elevations in the North American Vertical Datum of 1988 (NAVD88) and converted values to an elevation scaled to local tidal datums using $z^* = (z - \text{MTL}) / (\text{MHHW} - \text{MTL})$, where

z is the measured NAVD88 elevation, and mean tide level (MTL) and mean higher high water (MHHW) are local tidal datums measured in NAVD88 (Swanson et al., 2014). For interpretation, $z^* = 0$ indicates a wetland at mean tide level, inundated about 50% of the time, and $z^* = 1.0$ is a wetland at local mean higher high water and is inundated much less frequently.

To compute z^* , we obtained tidal datums (1985–2001 epoch) by processing time series of tidal channel water level collected near those sites with our own channel water level loggers, National Estuarine Research Reserve System water level stations (<https://cdmo.baruch.sc.edu/>), or NOAA tidal stations. We used VDATUM 3.6.1 and 4.1.2 for MTL estimates where needed. We processed water level time series using methodologies described in NOAA (2003).

Vegetation

For sites in the Coos and Columbia River estuaries, we obtained plant cover and height data during each GHG sampling event inside of the chambers to quantify biomass and species composition. We visually determined the percent cover of all species with at least 5% cover and measured the height of up to four random shoots of each species. From these measurements, we determined a “biomass index” by summing the product of average height and cover for all species.

Statistical analysis

For all statistical analyses, we used R (v. 4.0.2 and 4.0.3, R Core Team, 2020). We log-transformed CH_4 and N_2O data after adding a near-zero minimal constant to all values to remove negative values. We compared light and dark fluxes of the two gases with paired t-tests. Because these indicated little difference, we averaged light and dark flux data for all subsequent analyses.

For the full dataset (all wetland types pooled), we tested for relationships between major environmental drivers and log-transformed CH_4 fluxes with linear regression. We used the main well logger time series data as needed to fill in temperature and salinity data gaps in groundwater measures in the shallower wells at the time of gas sampling (e.g., when they were dry). Additionally, we explored whether environmental drivers sampled at each pair of chambers (such as salinity) were limiting factors (sensu Cade & Noon, 2003) on maximum CH_4 fluxes (estimated as the 0.95 quantile of the data distribution) with quantile linear regression using the R package “quantreg” (Koenker, 2005).

A prior GHG flux study in two Oregon estuaries examined a number of different machine-learning techniques and determined that boosted regression trees (BRT) provided the best predictive power when multivariate environmental drivers are measured (Schultz et al., 2023). Therefore, we developed BRT models to analyze the interactive and nonlinear effects of environmental drivers and wetland type on the full datasets of CH₄ and N₂O fluxes using the “gbm” package (Greenwell et al., 2022) and the “caret” package (Kuhn, 2022) for model training.

Boosted regression tree analysis is a machine learning method that sequentially combines multiple decision trees to develop a predictive model based on a matrix of continuous and/or categorical independent variables. This is done by training each subsequent tree by predicting the residual errors of the previous trees. The process of training multiple trees and combining their predictions is called “boosting.” By boosting multiple decision trees in this way, BRT models can capture complex relationships and make accurate predictions even on noisy, nonlinear data. BRT models also assess the relative importance of independent variables in determining the total variance in the model. To visualize model outputs, we used Individual Conditional Expectation (ICE) curves, which are an expansion of Partial Dependence Plots (PDPs). While PDPs show the average marginal effect on the response variable, ICE curves depict the change in the predicted response variable for each observation as each predictor variable varies. The centered ICE makes clearer any pronounced heterogeneity in our results.

After developing the BRT model for CH₄ based upon the point measures of fluxes and their paired environmental data, we implemented a slightly simplified version of the explanatory model in the predictive mode to estimate annual gas fluxes at the site level ($n = 34$). The environmental data we used to estimate annual fluxes were the one-year time series data collected at each site at 30 min intervals, including water-table level, groundwater salinity, groundwater temperature from continuous logging in the main wells, soil temperature from continuous logging at the main well, air temperature from nearby weather stations, and one-time point measurements of site elevation at the larger groundwater well, and the five categories of wetland class. We reran BRT models without groundwater pH in annual predictions since we did not have continuous site pH data over the study period (parameters only changed slightly). Predicted CH₄ fluxes per 30-min intervals were summed over one year to give an annual total per site. We chose not to estimate annual N₂O fluxes because of the relatively poor predictive power of the BRT model and their very low values (see below).

To test for differences across the five wetland types examined in this study (reference marsh, reference swamp, restored marsh, wet pastures, and dry pastures), we used parametric Welch’s one-way ANOVA and Games-Howell post hoc tests. We also reran this test after subdividing the flux measurements into wet (October–May) and dry (June–September) seasons.

For sites in the Coos and Columbia River estuaries, we examined relationships between GHG fluxes and plant metrics. We tested for relationships between GHG fluxes and the biomass index using linear regression. To examine potential linkages between plant community structure and GHG fluxes, we subset plant cover data inside of the GHG chambers collected in the summer season (June–August 2021) and applied 2-dimensional nonmetric multidimensional scaling (NMDS) to separate chambers by species composition using the R package “vegan” (v.2.6-2; Oksanen et al., 2022) and a Bray–Curtis dissimilarity matrix based on Wisconsin double-transformed cover data (Oksanen, 2015). A convergent solution was obtained after 20 iterations performed with the function “MetaMDS” and step-across similarities because many chambers had little overlap in species composition. On the NMDS plots, we overlaid centroids of selected plant species as well as contours of CH₄ and N₂O fluxes using the function “ordisurf” in “vegan,” which relates the dependent variable (GHG flux) to species composition in the ordination space with a general additive model.

RESULTS

Environmental drivers of CH₄ fluxes

There was no significant difference in CH₄ fluxes between light and dark conditions ($t = -0.03$, $df = 1338$, $p = 0.98$). Fluxes ranged from negative (uptake or consumption) to positive (emissions) values, with 16% of values showing CH₄ uptake or consumption, 16% showing non-detectable fluxes (treated as zeros), and 68% of values showing emissions to the atmosphere.

Linear relationships between CH₄ fluxes and key environmental drivers were weak due to substantial variability (low R^2) although often statistically significant (low p -values) within the large dataset (Table 1). Groundwater salinity, pH, and wetland elevation had negative relationships with CH₄ flux, while water-table level and groundwater temperature had positive relationships with CH₄ flux (Table 1; Appendix S1: Figure S1). The upper bounds of the CH₄ distribution with individual environmental drivers (e.g., an estimate of maximum short-term fluxes) similarly were positively or negatively related to

these drivers, indicating that several abiotic factors may have roles as limiting factors for CH₄.

We tuned the CH₄ BRT model using 2432 trees with an interaction depth of 16 and a learning rate of 0.01, and 11 as the minimum number of observations per node. The adjusted *R*² between the model trained with the full dataset against the full dataset was 0.86, indicating that it effectively captured the multi-factor, nonlinear controls over CH₄ fluxes. Three environmental drivers had a relatively strong influence on CH₄ fluxes in the BRT model, with wetland elevation accounting for 21.0% of relative influence, followed by salinity (18.3%) and water-table level (16.0%) (Figure 2; Appendix S1: Table S2). Wetland

type, pH, and air, soil, and groundwater temperature all had smaller relative effects on CH₄ fluxes in the model (each <15%).

Wetland elevation, water-table level, and salinity—the three most important variables in the BRT model—had nonlinear relationships with CH₄ fluxes when other variables were held constant (Figure 3). The highest positive flux values were observed at wetland elevations between about *z*^{*} = 0.5 and *z*^{*} = 0.8 (elevations somewhat below local MHHW). Furthermore, there was a dramatic decrease in CH₄ flux at about *z*^{*} = 1.4, corresponding to sites that were very infrequently inundated or not at all. Methane fluxes increased with higher

TABLE 1 Summary of linear relationships between point measurements of CH₄ fluxes and individual environmental drivers in Pacific Northwest (PNW) tidal wetlands shown in Appendix S1: Figure S1.

Environmental driver	Model fits to fluxes			Model fits to maximum fluxes	
	Slope	<i>R</i> ²	<i>p</i>	Slope	<i>p</i>
Salinity	−0.007	0.018	<0.001	−0.039	<0.001
Water-table level	0.277	0.060	<0.001	1.206	<0.001
Wetland elevation	−0.120	0.020	<0.001	−1.160	<0.001

Air temperature	−0.002	−0.0002	0.42	−0.006	0.62

Note: We fit fluxes with least-squares regression as well as maximum fluxes (0.95 quantile of the distribution) using quantile regression.

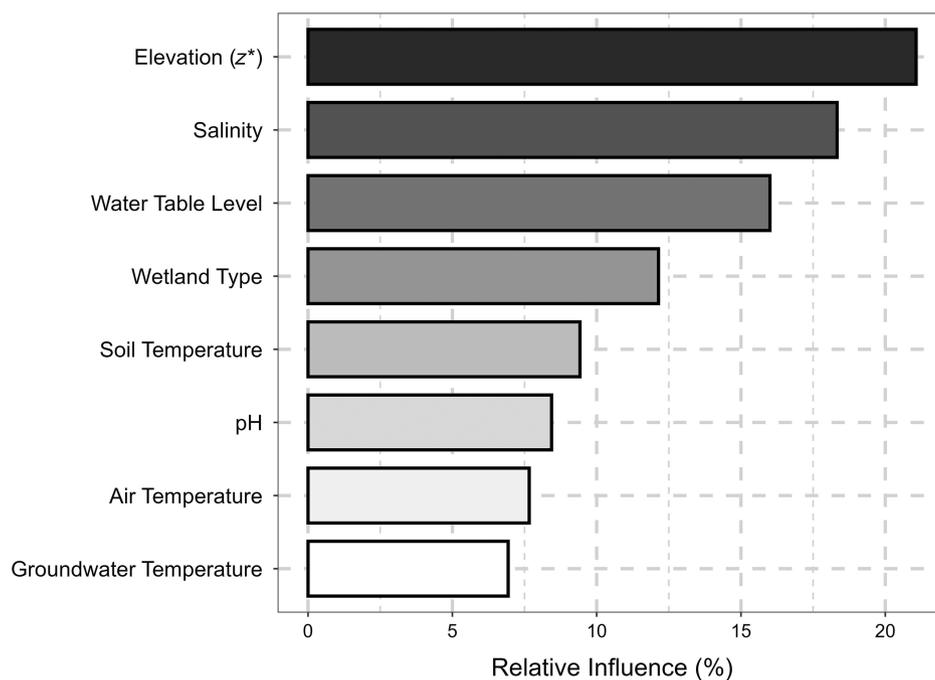

FIGURE 2 Relative influence of eight environmental variables on point measurements of CH₄ fluxes in the boosted regression trees (BRT) model for Pacific Northwest (PNW) coastal wetlands. The adjusted *R*² between modeled and measured fluxes was 0.86.

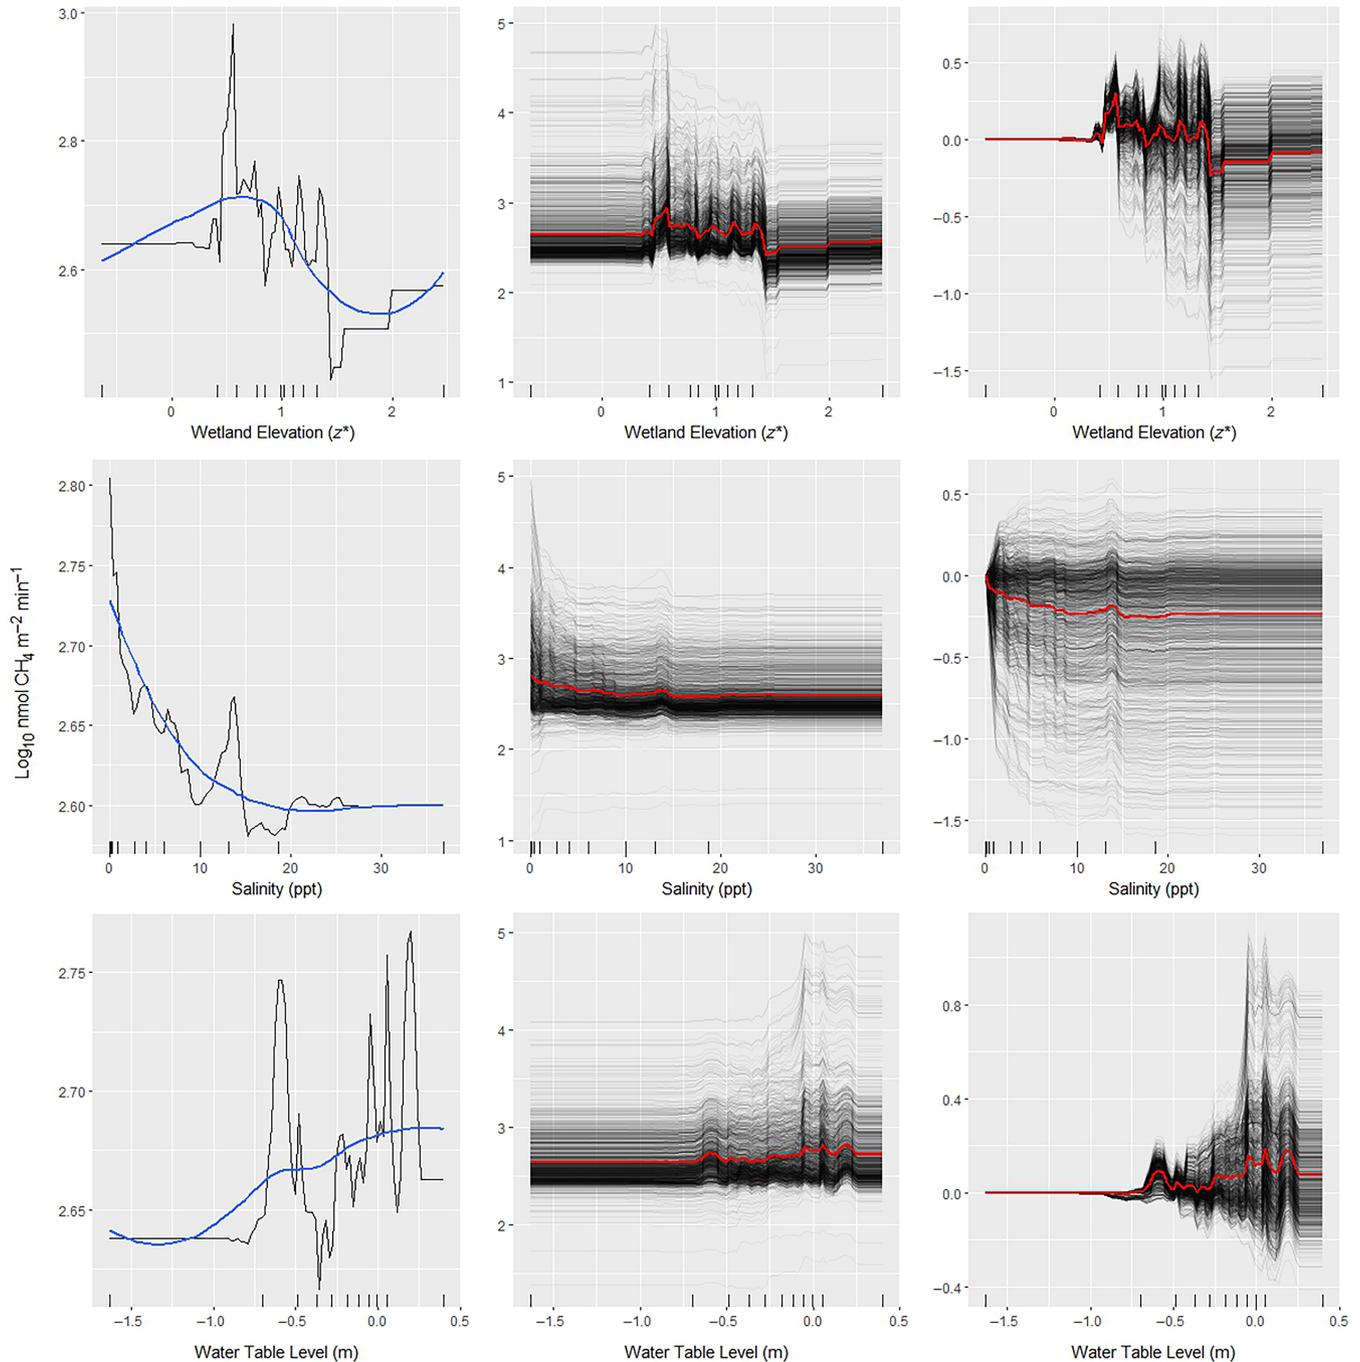

FIGURE 3 Partial (left), Individual Conditional Expectation (ICE) (center) and ICE-centered (right) plots of point measurements of CH_4 fluxes and the three most influential variables in the boosted regression trees (BRT) model. Loess-smoothed lines are in blue (left) or red (center, right). Rugs on the x-axis denote 10% quantiles of data. Partial plots show the influence of single variables on fluxes with other variables held constant.

water-table levels up to and above the surface (e.g., surface ponding), while deeper water-table levels (>0.5 m below the surface) were associated with lower CH_4 fluxes. Methane fluxes declined nonlinearly but monotonically with salinity, and when other variables were held constant, the lowest fluxes occurred at groundwater salinities above 15 ppt.

CH_4 fluxes and plant biomass and composition

Total plant biomass inside of the chambers, estimated as percent cover times height, was positively but only weakly linearly correlated with CH_4 fluxes ($r^2 = 0.08$, $p < 0.001$; Figure 4). In the NMDS plot of species

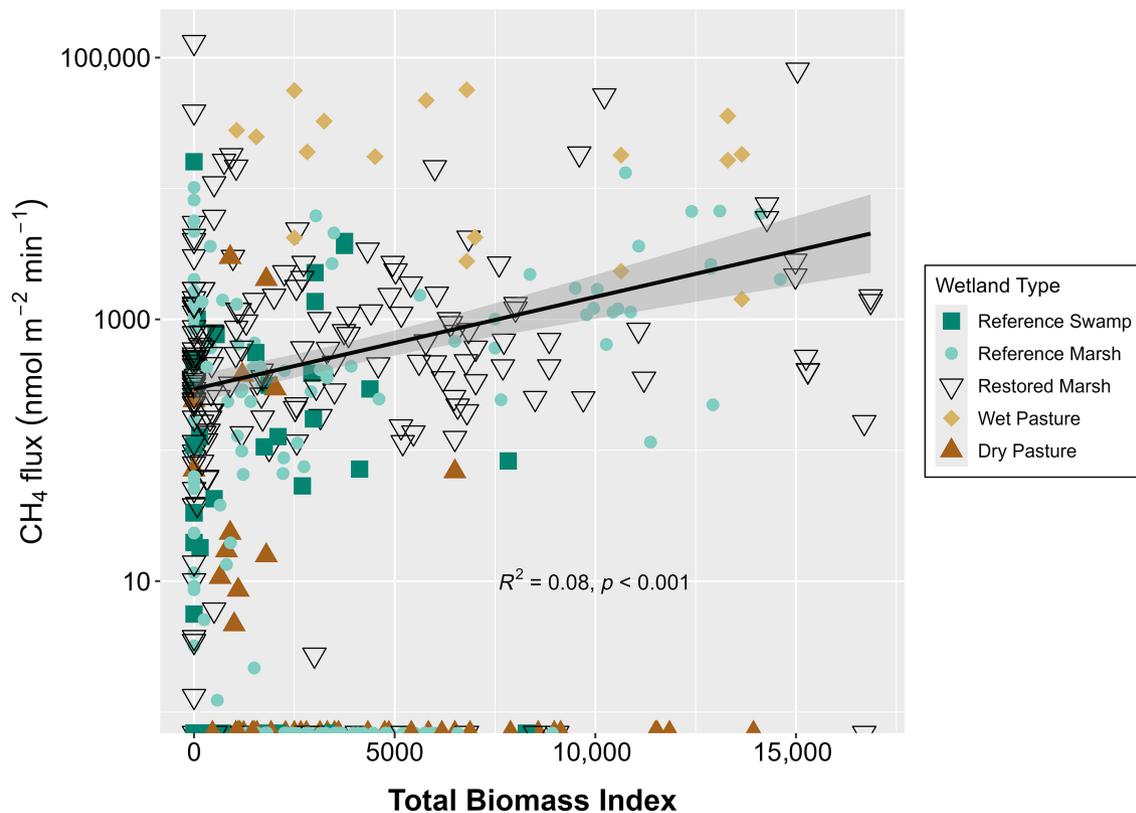

FIGURE 4 Relationship between plant biomass index and point measurements of CH₄ fluxes (log₁₀ scale). Data are from only the Coos and Columbia River estuaries but include all sampling dates over the course of a year.

composition with general additive models to visualize change in summertime CH₄ fluxes across the two-dimensional ordination, the highest CH₄ fluxes were observed in plots that tended to have a greater relative abundance of fresher species such as *Phalaris arundinacea* (reed canarygrass; a regionally invasive grass) and *Sagittaria latifolia* (wapato; a native forb) (Figure 5). In contrast, chambers dominated by regionally common native halophytic species such as *Salicornia pacifica* (pickleweed), *Distichlis spicata* (salt grass), and *Jaumea carnosa* (fleshy jaumea) had little to no CH₄ emissions or CH₄ uptake.

Wetland type effects on environmental drivers and point measurements of CH₄ fluxes

Large differences in environmental drivers among wetland types (Figure 6) largely subsumed the effect of type in the CH₄ BRT model (wetland type relative influence = 12.1%, Figure 2). Reference marshes had the highest groundwater salinity, followed by restored marshes and then other wetland classes. Restored marshes had the highest water-table levels, followed by reference marshes and wet pastures.

Wetland elevations were significantly higher in tidal swamps than in reference marshes, restored marshes, and wet pastures (while dry pastures were highly variable since they included three subsided former tidal wetlands and two pastures above tidal influence). Air, soil, and water temperature largely reflect seasonality, so differences among sites were small, with tidal swamps being slightly cooler and wet pastures slightly warmer (results not shown). Groundwater pH average and median across wetland types remained relatively consistent between 6.2 and 6.4.

When examined in isolation, CH₄ fluxes integrated over the duration of the study varied substantially among wetland types ($n = 1412$, $W = 47.4$, $df = 4$, $p < 0.001$; Figure 7A; Appendix S1: Table S4). The highest fluxes occurred in restored marshes and wet pastures. There was considerable variation in values within wetland classes; for example, in wet pasture sites, fluxes ranged from -31 to $\sim 200,000$ nmol m⁻² min⁻¹. Average fluxes were slightly higher in the dry season (which is also warmer), except in pasture sites. Wet pasture sites had the highest CH₄ emissions in the study, whereas dry pasture sites had the highest uptake value recorded (Appendix S1: Table S4). Restored marshes had maximum fluxes over 10 times higher than those in both reference tidal swamps and marshes.

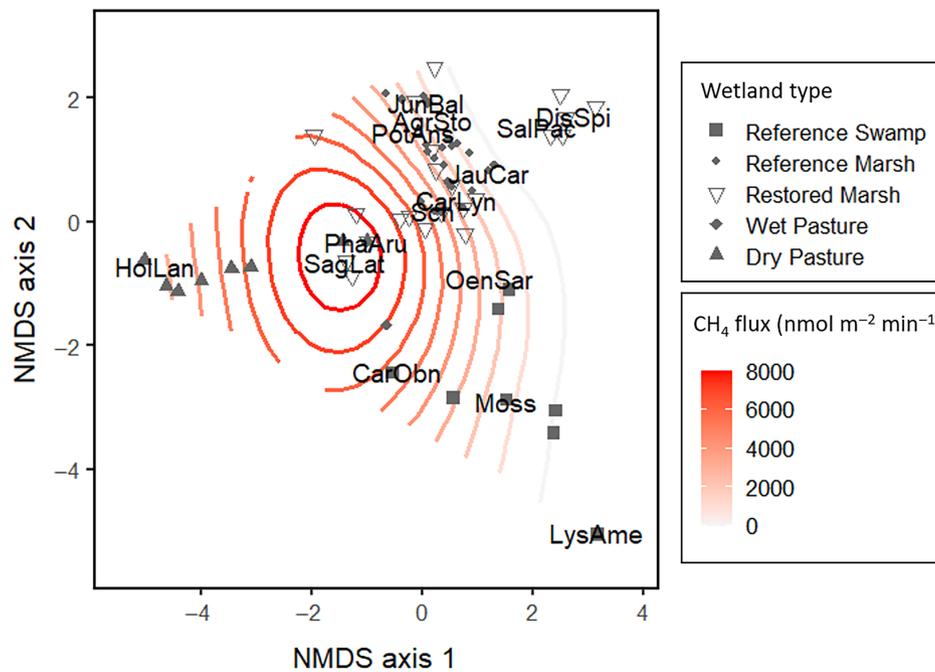

FIGURE 5 Relationship between plant species composition in two-dimensional nonmetric multidimensional scaling (NMDS) space and point measurements of CH_4 fluxes during summer sampling in the Coos and Columbia River estuaries. Individual chambers are indicated by points. The centroids of common and indicator species are given by three-letter codes as in Appendix S1: Table S3. Modeled CH_4 fluxes across the species compositional space are indicated by color contours.

During the wet season (October–May), CH_4 fluxes were significantly higher in restored marshes and wet pastures than in reference marshes and swamps, and significantly lower in dry pastures ($n = 983$, $W = 28.4$, $df = 4$, $p < 0.001$; Figure 7B). This pattern was similar for dry season conditions (June–September) except that wet pasture fluxes were highly variable and not different from any of the tidal wetland classes ($n = 429$, $W = 47.8$, $df = 4$, $p < 0.001$; Figure 7C).

Estimated annual CH_4 fluxes

Using the output from the BRT model and time series data, we estimated annual CH_4 fluxes over 2021–2022 (Table 2). To increase representation within our geographic study area, we included annual CH_4 fluxes from three additional reference sites and six additional restored sites in a large recently restored emergent marsh in Tillamook Bay, Oregon, reported by an earlier study that used a similar BRT modeling approach (Schultz et al., 2023). Annual fluxes are similar to those for point measurements, showing the highest annual CH_4 fluxes in restored marshes and wet pastures.

We also examined annual fluxes relative to average annual salinity and wetland elevation. Similar to the point measurements (Appendix S1: Figure S1), there was

wide variability in annual CH_4 fluxes at salinities < 3 ppt, but a much narrower range of fluxes at higher salinities (Figure 8A). The result of this variability was that salinity classes were not significantly different whether fresh and oligohaline classes were separated or combined (Welch's ANOVA $p > 0.60$, Table 3). Annual and point measurements of fluxes by wetland and salinity classes are given in Appendix S1: Tables S4 and S5. Higher annual CH_4 fluxes ($> 10 \text{ g CH}_4 \text{ m}^{-2} \text{ year}^{-1}$) were only observed in lower elevation wetlands, where $z^* < 0.75$ (Figure 8B).

Environmental drivers of nitrous oxide fluxes

As with CH_4 fluxes, there was no significant difference in N_2O fluxes under dark versus light conditions ($t = 1.31$, $df = 445$, $p = 0.19$), and therefore, we averaged light and dark fluxes for each chamber measurement. The majority of flux measurements (89.5%) were below the detection limit (treated as zeros), while 8.4% were emissions and 2.1% were uptake.

Nitrous oxide fluxes were only significantly linearly related to water-table level but with low predictive power ($R^2 = 0.030$, Appendix S1: Table S6). In the BRT model, the environmental drivers explained a modest amount of the variation in measured fluxes (adjusted $R^2 = 0.25$).

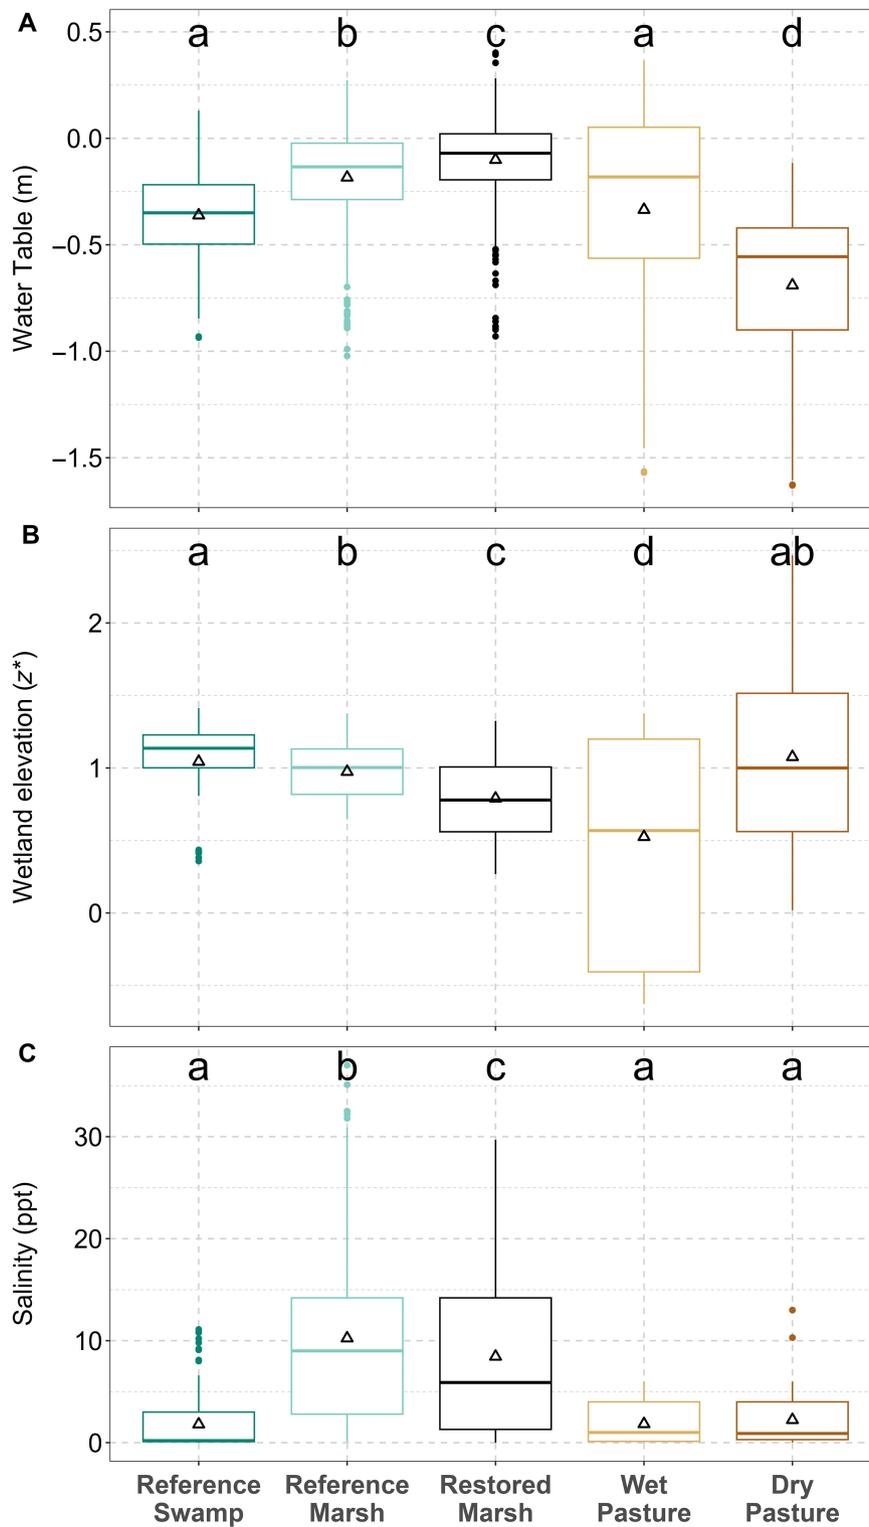

FIGURE 6 Boxplots of differences in water table (A), elevation (B), and groundwater salinity (C) by wetland type. Median = solid lines, mean = triangles. Unshared letters denote significant differences (Welch's ANOVA, Games-Howell tests).

Wetland type was the strongest predictor of N₂O fluxes (22.0%) while other factors had lower relative importance, including water-table level (19.3%), wetland elevation (15.9%), and salinity (12.2%) (Figure 9; Appendix S1: Table S2).

Total plant biomass was not significantly correlated with N₂O fluxes ($R^2 = 0.007$, $p = 0.32$). When chambers were evaluated in terms of species composition, the highest N₂O fluxes tended to be associated with *Holcus lanatus* (a non-native grass found in dry pastures) while

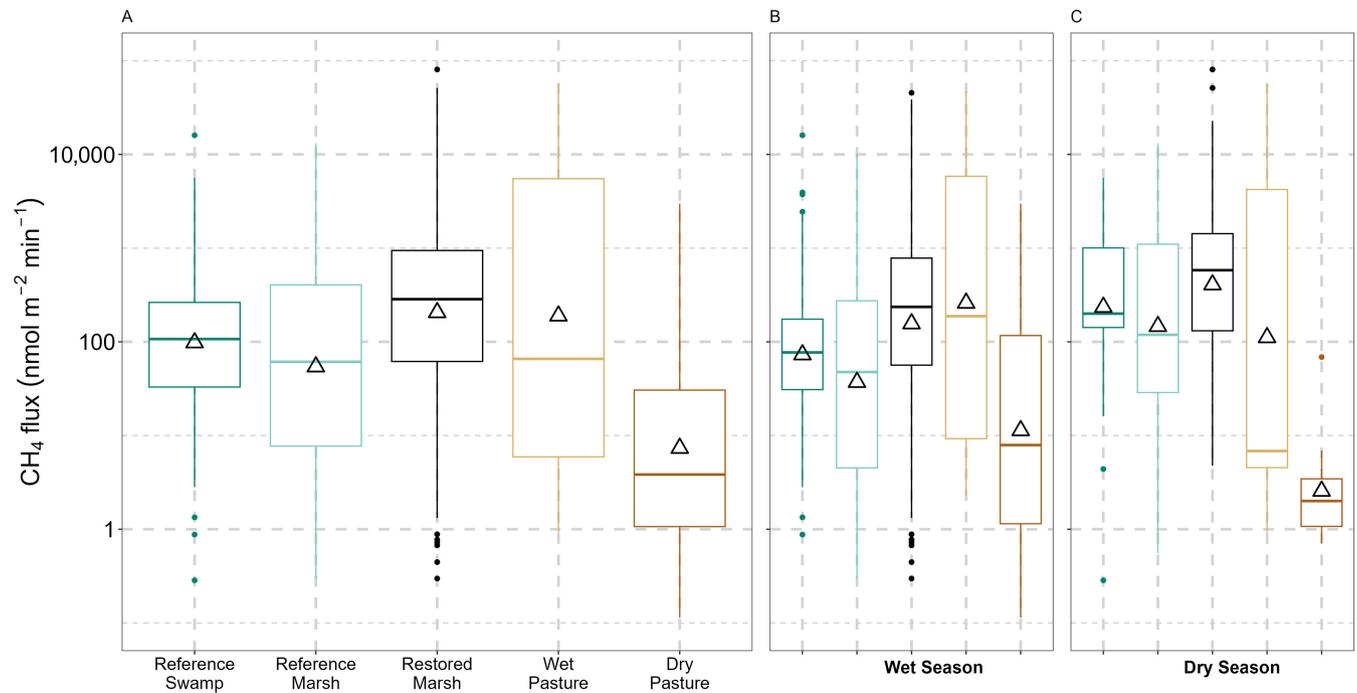

FIGURE 7 Boxplots of point measurements of CH₄ flux by wetland type in all seasons (A) and separated into wet (B) and dry (C) seasons in Pacific Northwest (PNW) estuaries (log₁₀ scale). Median = solid lines in the box plots, mean = triangles. Wetland classes not sharing the same lowercase letters were significantly different.

TABLE 2 Annual CH₄ fluxes for wetland classes predicted from the boosted regression tree (BRT) model.

Predicted CH ₄ flux (g CH ₄ m ⁻² year ⁻¹)						
Wetland class	N	Mean	SE	Median	Max	Min
Reference swamp	5	0.56 a	0.15	0.58	0.96	0.08
Reference marsh	15	4.44 b	2.18	2.03	34.61	0.75
Restored marsh	15	36.30 b	27.77	3.94	420.03	0.46
Wet pasture	3	37.25 ab	34.61	3.60	106.46	1.70
Dry pasture	5	0.21 ab	0.84	0.14	3.26	-1.39

Note: Included are all sites from this study and three additional reference marshes and six additional restored marshes in Tillamook Bay, OR, reported by Schultz et al. (2023). Unshared letters in the mean column denote significant differences (Welch's ANOVA, Games-Howell tests).

the lowest fluxes were associated with native freshwater wetland species such as *Carex obnupta*, *Oenanthe sarmentosa*, and mosses (Appendix S1: Figure S2).

Wetland type effects on nitrous oxide fluxes

Nitrous oxide fluxes differed significantly by wetland class (chi-squared = 32.876, df = 4, $p < 0.001$), although their medians were all zero (Appendix S1: Table S7). Dry pasture sites had higher fluxes than wet pastures, reference, and restored marshes, and tidal swamps (post hoc Dunn's test). Least-disturbed marshes showed the

greatest variability in fluxes, with a maximum of 49 and a minimum of -60 nmol N₂O m⁻² min⁻¹. Reference and restored marshes each showed approximately equal flux ranges above and below zero.

DISCUSSION

Blue carbon ecosystems are recognized as potential contributors to natural climate solution initiatives to help mitigate anthropogenic emissions. Because GHG emissions, particularly CH₄, may partially or completely offset the substantial carbon sequestration rates of tidal wetlands (Al-Haj & Fulweiler, 2020; Bridgman et al., 2006;

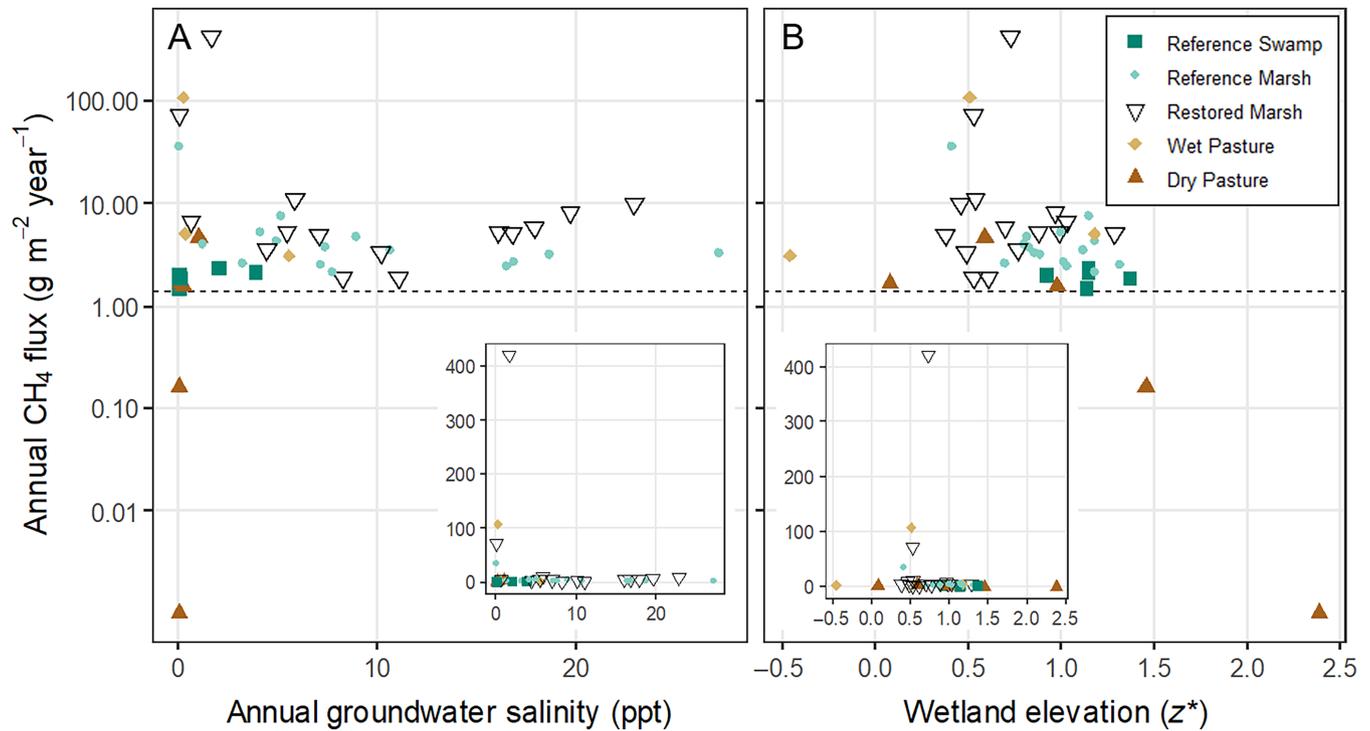

FIGURE 8 \log_{10} annual CH_4 flux (plus a constant of 1.393) relative to (A) average annual groundwater salinity and (B) standardized tidal elevation (z^*) from 34 sites in this study and nine sites in Schultz et al. (2023). Wetland classes are shown by different colors and shapes. The insets show non-logged results without the added constant.

TABLE 3 Annual CH_4 fluxes for salinity classes predicted from the boosted regression tree (BRT) model.

Predicted CH_4 flux ($\text{g CH}_4 \text{ m}^{-2} \text{ year}^{-1}$)						
Salinity class	N	Mean	SE	Median	Max	Min
Fresh	11	19.45	11.01	0.46	106.46	-1.39
Oligohaline	10	44.27	41.75	2.73	420.03	0.72
Mesohaline	18	2.86	0.54	2.20	9.61	0.46
Polyhaline	4	4.67	1.69	4.28	8.36	1.74

Note: Included are all sites from this study and two oligohaline and seven mesohaline sites in Oregon from Schultz et al. (2023).

Rosentreter et al., 2023), and could thus limit the viability of estuarine wetlands as a climate mitigation strategy (Johannessen & Christian, 2023; Silva et al., 2022), it is essential to quantify their effects on the potential climate benefits of conserving and restoring tidal wetlands. It also is important to predict the local and regional variability of GHG fluxes associated with those activities for the benefit of planners, land managers, policymakers, and others developing natural climate solution initiatives and prioritizing actions.

To address these issues, we collected a large dataset of CH_4 and N_2O fluxes and associated environmental drivers across multiple wetland types and management regimes in estuarine wetlands in the PNW and compiled these new data with previously reported regional data for

analysis. Our results identify the degree of soil saturation (as indicated by both water-table level and wetland surface elevation) and groundwater salinity as major drivers of CH_4 fluxes. In turn, the effects of wetland type and management on GHG fluxes was largely mediated through their effects on these environmental drivers.

Reflecting the current and legacy effects of land management on these environmental drivers, wet pastures and restored marshes (mostly previously diked pastures) had the highest CH_4 fluxes, albeit with high variation among sites. In a more limited dataset from sites in only two estuaries, N_2O fluxes were uniformly low across all wetland types and land management regimes with a median of zero, suggesting this is not an important GHG in many PNW estuarine wetlands. We show that a

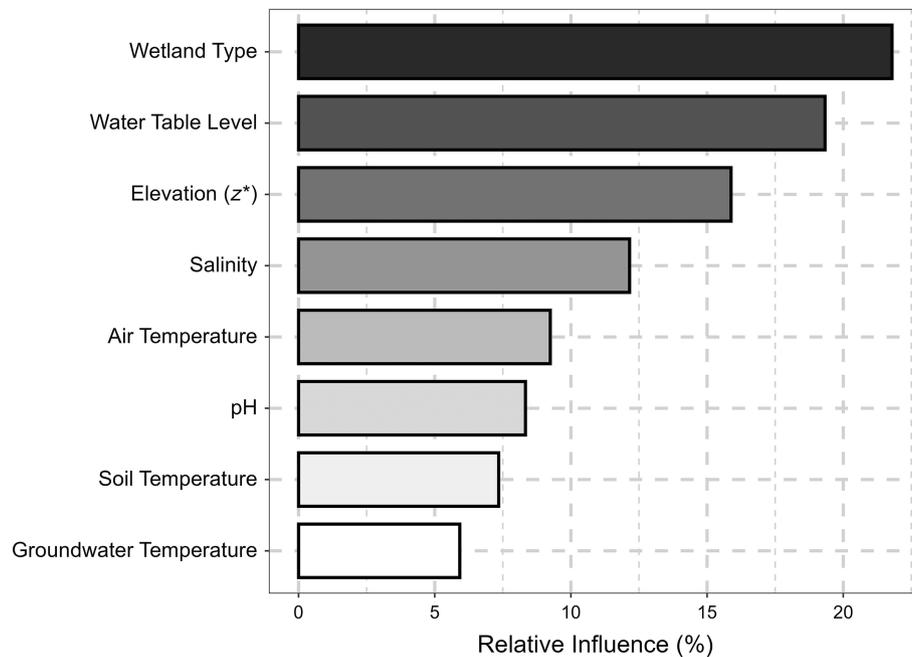

FIGURE 9 Relative influence of eight environmental variables on point measurements of N_2O fluxes in the boosted regression trees (BRT) model for Pacific Northwest (PNW) coastal wetlands. The adjusted R^2 between the model and measured fluxes was 0.25.

machine learning approach can be used to estimate annual CH_4 fluxes across heterogeneous landscapes if key environmental time series data are collected, and the regional models developed should allow extrapolation to other tidal wetland sites in the PNW.

Environmental controls of CH_4 fluxes

Our results largely support our first hypothesis that CH_4 fluxes increase with higher water tables, lower salinity, and higher soil and air temperatures. Additionally, the machine learning model supported our second hypothesis that these variables had nonlinear and interactive effects. The environmental drivers individually had poor, even if often statistically significant, linear relationships with CH_4 fluxes (Table 1, Appendix S1: Figure S1). However, BRT modeling successfully captured these complex relationships, explaining 86% of the variation in CH_4 fluxes, which improves upon previous BRT modeling of CH_4 fluxes in two Oregon estuaries using a somewhat different set of environmental driver variables ($R^2 = 0.77$, Schultz et al., 2023). The most important variables in the BRT model were related to hydrology, with wetland elevation relative to tide range (a proxy for surface inundation at tidal sites) and water-table level (important at both tidal and nontidal sites) together explaining 37% of the variance (Figure 2). Salinity was also important, explaining 18% of the variance. The partial plots from the

BRT model demonstrated the nonlinear relationship of these variables with CH_4 fluxes (Figure 3).

We expected variables relating to the degree of waterlogging to be important in explaining CH_4 fluxes because methanogenesis is an obligatory anaerobic process and aerobic CH_4 oxidation requires oxygen (Meronigal et al., 2004). Our results emphasize the importance of measuring site elevation normalized to tide range (z^*) as a predictive variable for CH_4 fluxes in tidal wetlands, similar to the findings of Arias-Ortiz et al. (2024) in a synthesis of CH_4 fluxes across tidal wetlands in the conterminous United States. In comparison, water-table level can be more problematic as a predictive variable for point chamber measurements of gas fluxes because these measurements are often taken during low tides and in daylight hours. We sampled all but the lowest elevation tidal sites randomly through the daylight hours, which should reduce the tidal bias in our analysis (potential daylight sampling biases are discussed below). The effect of water-table level can also be complicated. For example, a PNW salt marsh chamber study with continuous diel sampling found that CH_4 flux decreased during a storm surge, which was ascribed to hydrostatic pressure inhibiting diffusion and ebullition (i.e., bubble release) (Diefenderfer et al., 2018a). Similarly, eddy covariance studies often find pulses of CH_4 flux around low tides, suggesting that the inhibiting effect of hydrostatic pressure may be a widespread phenomenon (Arias-Ortiz et al., 2024).

Salinity was the second most important variable in our CH₄ BRT model (Figure 2). It is recognized as an important predictor of CH₄ fluxes in tidal wetlands because it is a surrogate for less easily measured sulfate concentrations (Poffenbarger et al., 2011). Seawater has relatively high concentrations of sulfate, and sulfate-reducing bacteria in wetlands are competitively superior to methanogens for substrates (Magonigal et al., 2004). However, variability in this relationship can be high because of the local depletion of groundwater sulfate under saline conditions (Poffenbarger et al., 2011). We found very high modeled annual fluxes of CH₄ (i.e., >10 g CH₄ m⁻² year⁻¹) only at salinities less than about 2 ppt, albeit with substantial variation due to interacting factors such as water-table level and site elevation (Figure 8). Both measured data (Appendix S1: Figure S1) and the BRT model (Figure 3) of instantaneous fluxes showed a slight spike in CH₄ emissions at about 15 ppt salinity, but this result was not evident in the annual estimates. Thus, we conclude that some, but far from all, fresh and oligohaline tidal wetlands in the PNW emit large amounts of CH₄. Similar results have been found in syntheses over broader geographic areas (Al-Haj & Fulweiler, 2020; Arias-Ortiz et al., 2024; Poffenbarger et al., 2011; Windham-Myers et al., 2018). We return to the management implications of these findings below.

The relatively low influence of temperature in our CH₄ BRT model (Figure 2) was surprising given the strong theoretical foundation for temperature effects on methanogenesis (Wu et al., 2021) that typically is translated into robust empirical relationships across wetland sites. For example, temperature was a dominant predictor of CH₄ fluxes in both chamber studies and eddy covariance studies in tidal wetlands across the conterminous United States (Arias-Ortiz et al., 2024). Apparently, in our dataset, the gradients of salinity and waterlogging among sites were more important than the relatively muted seasonal temperature changes along the PNW coast in controlling CH₄ fluxes. However, in our previous study of CH₄ fluxes in two Oregon estuaries, temperature was the most important predictor of CH₄ fluxes in the BRT model (Schultz et al., 2023).

Plant controls of GHG fluxes

Our third hypothesis was that plant biomass and community composition would affect GHG fluxes. There was a weak but significant relationship between our plant biomass index and CH₄ fluxes (Figure 4), but not with N₂O fluxes. Plant community composition was also related to both CH₄ and N₂O fluxes (Figure 5, Appendix S1:

Figure S2). The highest CH₄ fluxes tended to be associated with plots with greater abundance of *Phalaris arundinacea* and *Sagittaria latifolia*, most likely reflecting the preference of these species for freshwater conditions (Borde et al., 2020). *P. arundinacea* is a regionally common invasive grass that often dominates diked former tidal wetlands but also occurs in fresher tidal sites. *S. latifolia* is a native forb common in tidal freshwater wetlands in the Columbia River Estuary. Plants can also have direct effects on wetland CH₄ fluxes by affecting CH₄ transport from the soil to the atmosphere, diffusion of O₂ into the root zone, and by providing labile substrate (Bridgman et al., 2013; Laanbroek, 2010; Vroom et al., 2022). However, differences in species composition and their physiological traits may not drive GHG fluxes per se, since differences in plant composition in tidal wetlands often closely reflect the same major environmental drivers that affect CH₄ fluxes such as inundation (elevation) and salinity (Janousek & Folger, 2014; Watson & Byrne, 2009). Other studies have similarly found that plant species composition can be an effective predictor of CH₄ fluxes because of these indirect relationships between plant environmental tolerances and environmental drivers of CH₄ flux (Bubier et al., 1995; Dias et al., 2010). Plants likely have the same range of effects on N₂O fluxes, but plant effects are complicated by the multiple pathways of N₂O production and consumption discussed below. Also, the low N₂O fluxes measured in this study would tend to reduce any strong associations with plant biomass or composition.

We found no effect of light versus dark conditions on the fluxes of either CH₄ or N₂O, but this is not the equivalent of finding that there were no day versus night differences. For example, a previous study found that a PNW salt marsh had greater nighttime than daytime CH₄ fluxes (Diefenderfer et al., 2018a). We may have observed limited light versus dark differences in GHG fluxes because plant stomata typically close upon intermittent darkness after a lag period of tens of minutes (Lawson & Blatt, 2014), so our short incubation conditions may have had limited effects on plant gas transport. Furthermore, the wetland plants in our plots were primarily herbaceous emergent species that occur in shallower water, where passive diffusion is the dominant mode of gas flow (Vroom et al., 2022). Diffusive gas flow through plants is limited mainly by root properties, and accordingly, there is typically no diel pattern in gas flux from these plants (Vroom et al., 2022). To our knowledge, only one taxon in our dataset, *Schoenoplectus* spp., has limited capability for pressurized gas flow where stomatal effects on gas fluxes would be expected to be more important (Vroom et al., 2022). Finally, there were also limited chamber effects on air or soil temperatures with our short

incubation times, so typical diel temperature changes were not represented by our light versus dark incubation conditions.

Wetland type and management effects on CH₄ fluxes

We confirmed our fourth hypothesis that CH₄ fluxes differ among estuarine wetland types and land management regimes, which can largely be explained by their effects on the ecosystem drivers of fluxes such as elevation and water-table level. Furthermore, our study indicated that the highest CH₄ fluxes occurred in sites that are fresher and more waterlogged, such as nontidal wet pastures and lower salinity restored sites (Figure 8). Wetland type (which included management categories) was only the fourth most important factor in the CH₄ BRT model, explaining 12.1% of the variation (Figure 2). This relatively lower importance may be due to our finding that the important environmental drivers of CH₄ flux (elevation, salinity, and water-table level) also differed substantially among wetland types (Figure 6). Thus, wetland type and management have a large effect on the environmental factors that ultimately control CH₄ fluxes. A similar conclusion emerged from our previous study using BRT modeling in the PNW (Schultz et al., 2023). Temperature variables were less important in the BRT model in the current study but would be expected to reflect diel and seasonal effects rather than site effects in a regional analysis with limited variability in climate regime (Appendix S1: Table S1).

Consistent with Schultz et al. (2023), we found that restored marshes and wet nontidal pastures tended to have the highest average, median, and maximum CH₄ fluxes, but there was wide variation within these wetland categories (Table 2). Both restored marshes and wet pastures tended to be at lower elevations than reference sites, reflecting prior subsidence from drainage and soil compaction (Figure 6). Restored marshes had high water-table levels and variable salinity, whereas wet pastures had variable water-table levels and low salinity. Accordingly, two of three low salinity restored marshes had very high annual CH₄ fluxes (Figure 8). Wet pastures were distinctly more waterlogged than dry pastures, but they still had substantial variation in water tables (Figure 6), which led to their large variation in CH₄ fluxes.

N₂O fluxes

We also confirmed our fifth hypothesis that N₂O fluxes are low overall, but are somewhat higher in

nontidal pastures. The median N₂O flux was zero in all wetland types, but average and maximum fluxes were somewhat higher in dry pasture sites (Appendix S1: Table S7). All wetland types also had a substantial number of significantly negative N₂O fluxes. Our findings agree with other studies in the PNW and elsewhere that wetlands have low N₂O fluxes unless they have substantial external nitrogen inputs (Diefenderfer et al., 2018a; Moseman-Valtierra, 2012; Schultz et al., 2023).

Because the majority of our N₂O measurements were below detection level, the BRT model did a relatively poor job of predicting drivers of fluxes ($R^2 = 0.25$). This result is perhaps not surprising given that N₂O is produced by several processes within the nitrogen cycle, which have very different environmental controls, and different components of the denitrification process produce and consume N₂O (Baggs, 2011; Butterbach-Bahl et al., 2013). Reflecting the inability of the BRT model to capture important environmental drivers of N₂O fluxes, wetland type was the most important variable in the model (Figure 9).

These results are substantially similar to our previous study of GHG fluxes in two Oregon estuaries, where N₂O fluxes had a median of zero and the BRT model only predicted 11% of the total variance (Schultz et al., 2023). In that study, we found that former tidal wetlands in agricultural use and restored sites had the highest (but still low) N₂O fluxes, suggesting that sites restored from an agricultural legacy may retain some legacy effects that promote slightly higher N₂O fluxes.

Synthesis and management considerations

This study demonstrates that machine-learning techniques, combined with an appropriate set of environmental driver data, are a powerful tool for estimating GHG fluxes from tidal wetlands. This approach may provide an alternative to intensive chamber-based or flux tower measurements, which are labor-intensive and expensive and, therefore, may not be feasible for many tidal wetlands where assessment of GHG fluxes is needed to understand the radiative forcing of these ecosystems. Our results can be directly used in other tidal wetlands in the PNW. A similar approach in other regions would require collecting GHG flux and environmental driver data across the spectrum of wetland conditions in that region, or using existing data if available, and performing the appropriate machine-learning techniques.

In the absence of site-specific measurements, different salinity thresholds for estimating high versus low CH₄ emissions from tidal wetlands have been proposed and are widely cited in the scientific literature. Poffenbarger

et al. (2011) proposed a salinity threshold of 18 ppt above which “the methane emitted by a tidal marsh will be less (in CO₂ equivalent units) than the carbon dioxide sequestered as soil carbon in most (95%) tidal marshes.” The IPCC Wetland 2013 Supplement (2014) in their Tier 1 emission factors also proposed an 18-ppt salinity threshold, where sites >18 ppt have no CH₄ emissions and sites <18 ppt have emissions of 19.4 g CH₄ m⁻² year⁻¹. No rationale for this threshold is given in the IPCC Supplement, but Poffenbarger et al. (2011), among others, were cited as criteria. Arias-Ortiz et al. (2024) in a recent synthesis of tidal wetland CH₄ fluxes from the conterminous United States (that included data from PNW tidal wetlands reported in Schultz et al. (2023)), suggested more refined IPCC Tier 1 CH₄ emissions factors based upon salinity, elevation class, and average annual daily maximum air temperature (MAT_{max}). Fresh/oligohaline sites in low and mid elevation classes and mesohaline sites with MAT_{max} > 19°C had consequential CH₄ emissions (mean >21.5 g CH₄ m⁻² year⁻¹). However, this synthesis did not consider CH₄ fluxes in the context of the radiative balance of a site in setting thresholds, in contrast to Poffenbarger et al. (2011).

Our data suggest that the salinity threshold of IPCC (2014) would overestimate or underestimate emissions for many estuarine wetlands in the PNW depending on their salinity and tidal elevation. Our results are in general agreement with Arias-Ortiz et al. (2024). The MAT_{max} of our sites ranges between 14 and 16°C (Appendix S1: Table S1), putting our mesohaline sites in the lower tier of CH₄ emissions according to Arias-Ortiz et al. (2024). Correspondingly, we found emissions exceeding 10 g CH₄ m⁻² year⁻¹ only at salinities below 2–3 ppt (Figure 8). Our fresh/oligohaline reference marshes and tidal forest sites were mostly high elevation sites relative to tides (Appendix S1: Table S1), and they also tended to have low CH₄ emissions (reference swamp and reference marsh mean = 0.6 and 9.0 g CH₄ m⁻² year⁻¹, respectively, Appendix S1: Table S5). We address CH₄ fluxes in the context of the radiative balance of tidal wetlands, similar to Poffenbarger et al. (2011), below.

We plan to compare the effects of CH₄ fluxes versus soil carbon sequestration on the radiative balance of many of these research sites in a future publication, but we can gain perspective here by comparing the average soil carbon accumulation rate for brackish and salt marshes on the Pacific coast of North America, 634 g CO₂ eq m⁻² year⁻¹ (2 SE = 337; Windham-Myers et al., 2018). We found CH₄ emissions at >2 ppt salinity to range from 0.5 to 9.6 g CH₄ m⁻² year⁻¹ (Figure 8), which equates to 44 to 922 g CO₂ eq m⁻² year⁻¹ (2 SE = 86) using a 20-year sustained-flux global

warming potential (SGWP) and from 21 to 432 g CO₂ eq m⁻² year⁻¹ (2 SE = 40) with a 100-year SGWP (Neubauer & Megonigal, 2015). Thus, this preliminary analysis suggests that the radiative balance of brackish and saline wetlands over 2 ppt in the PNW is generally positive (i.e., cooling) with a 100-year SGWP but is more site-specific with a 20-year SGWP. Nonetheless, the operative word above for the 100-year SGWP is “generally” given the large variation in both soil carbon accumulation rates and CH₄ fluxes. Thus, we suggest that CH₄ fluxes be considered in the climate balances of all PNW estuarine wetlands regardless of salinity when weighing the climate effects of management actions. Most PNW estuarine wetlands with a salinity >2 ppt will have a net cooling radiative balance with a 100-year SGWP, but the substantial effect of CH₄ fluxes on the radiative balance is essential to consider if a quantitative analysis of the climate benefits of management actions is a goal. Our results clearly show that IPCC default values for CH₄ fluxes are inappropriate in PNW estuarine wetlands.

Based upon the current analysis, we can make some preliminary best-management practice suggestions for the PNW. Given the very high CH₄ fluxes we observed in some diked wet pasture sites, restoration focused on former tidal wetlands with a high water table may have the greatest impact on reducing GHG emissions, provided that restoration actions lower the water table. A beneficial change in emissions will be particularly large if the site converts from a freshwater or oligohaline state to a more saline condition upon restoration. We expect less climate benefit from restoring dry pastures, although many other ecosystem benefits will accrue in such sites. According to our findings, restored marshes are second only to wet pastures in CH₄ emissions, but we suggest that as sites evolve (Simenstad & Thom, 1996), they will have lower CH₄ emissions as they approach greater functional recovery.

Restored tidal wetland sites in the PNW are typically at a lower elevation than reference sites because of past subsidence (Frenkel & Morlan, 1991). If fill is used in the restoration process to create a higher wetland, then lower CH₄ fluxes would be expected regardless of the site's salinity. Excavation to restore tidal channel networks can result in material useful for creating higher elevation wetland areas within a site (Diefenderfer et al., 2018b), though such an approach presents permitting, ecological, and logistical challenges (Piercy et al., 2023). Effective tidal drainage from a restored site, such as the construction of a channel network of sufficient density, could also reduce CH₄ fluxes by lowering the water table during low tide periods. Over time, lower elevation restored marshes accrete sediment and gain elevation, but it may take many decades for them to reach similar elevations to

their reference counterparts (Cornu & Sadro, 2002; Thom, 1992). Typical rates of reference marsh accretion in the PNW range from 0.8 to 4.1 mm year⁻¹ across a wide range of fluvial suspended sediment load (Peck et al., 2020; Thom, 1992). Yet, accretion rates up to an order of magnitude higher have been reported in some PNW estuaries, including in reference and restored sites in the Columbia Estuary (7–24 mm year⁻¹; Diefenderfer et al., 2008, 2021), suggesting that some restoration sites may be capable of reaching reference wetland elevations more quickly, which may lead to reductions in CH₄ emissions.

Another recommended focus of restoration in PNW estuaries is tidal swamps, which were once widespread in the PNW with a greater extent than marshes but are now almost completely lost (Brophy, 2019). Swamp restoration may have a substantial climate benefit in fresh-oligohaline conditions where the restoration of marshes may yield less carbon accumulation and long-term storage. Forested tidal swamps tend to require a higher tidal elevation for persistence (Brophy et al., 2011), but the high carbon stocks in both tree biomass and soils in the relatively few extant tidal swamps (Kauffman et al., 2020) suggest they have among the highest capacities for total ecosystem carbon stocks accumulation globally of any blue carbon ecosystem.
